Viscoelastic Material Models for more accurate Polyethylene Wear Estimation

Gioacchino Alotta\textsuperscript{1}, Olga Barrera\textsuperscript{2,3} and Elise C. Pegg\textsuperscript{4}

Abstract
Wear debris from ultra-high molecular weight polyethylene (UHMWPE) components used for joint replacement prostheses can cause significant clinical complications, and it is essential to be able to predict implant wear accurately \textit{in vitro} to prevent unsafe implant designs continuing to clinical trials. The established method to predict wear is simulator testing, but the significant equipment costs, experiment time and equipment availability can be prohibitive. It is possible to predict implant wear using finite element methods, though these reported in the literature simplify the material behaviour of polyethylene and typically use linear or elastoplastic material models. Such models cannot represent the creep or viscoelastic material behaviour and may introduce significant error. However, the magnitude of this error and importance of this simplification has never been determined. This study compares the volume of predicted wear from a standard elastoplastic model, to a fractional viscoelastic model. Both models have been fitted to experimental data. Standard tensile tests in accordance with ISO 527-3 and tensile creep-recovery tests were performed to experimentally characterise both (a) the elastoplastic parameters and (b) creep and relaxation behaviour of the ultra-high molecular weight polyethylene. Digital image correlation technique was used in order to measure the strain field. The predicted wear with the two material models was compared for a finite element model of a mobile-bearing unicompartmental knee replacement, and wear predictions were made using Archard’s law. The fractional viscoelastic model predicted almost ten times as much wear compared to the elastoplastic material representation. This work quantifies, for the first time, the error in produced by use of a simplified material model in polyethylene wear predictions, and shows the importance of representing the viscoelastic behaviour of polyethylene for wear predictions.

Polyethylene wear; material model; fractional viscoelasticity; unicompartmental knee arthroplasty; finite element analysis

Introduction
Wear of ultra-high molecular weight polyethylene (UHMWPE) components used for joint replacement prostheses can cause significant clinical complications, such as: implant loosening, osteolysis, inflammatory responses and post-operative pain \textsuperscript{(1)}. It is, therefore, essential to be able to predict implant wear as accurately as possible \textit{in vitro}, to minimise the risk of unsafe implant designs continuing to clinical trials. The established method to predict the wear of an implant is with simulator testing. Wear simulator tests have been well characterised and validated against clinical data, and can predict implant wear to an acceptable degree of accuracy so is regularly used for validation of new designs \textsuperscript{(2)}. However, wear simulator tests require significant equipment costs, a availability of equipment is limited, and the experiments take a long time \textsuperscript{(3)}.

Numerical simulation provides an alternative method to predict wear. Maxian \textit{et al}. were the first researchers to use discretisation to predict linear wear from a finite element model of an UHMWPE hip replacement component \textsuperscript{(4, 5)}. Maxian’s work was based on a study by Marshak and Chen \textsuperscript{(6)} who proposed that by applying Archard’s wear equation to discrete elements of the articulating surfaces, non-uniform contact pressures and geometries could be taken into account. Maxian \textit{et al}. applied Marshak’s approach to finite element models of an UHMWPE acetabular cup. The linear wear, or wear depth, \((\delta h)\) was calculated for each individual node on the articulating surface for each time increment \((\Delta t_i)\) from the contact stress \((\sigma)\), the sliding distance \((S)\) and the wear factor \((K_w)\) (Equation 1). Using this equation, the total wear for one cycle of loading was calculated for each node. To account for geometrical changes resulting from the wear, at a chosen number of cycles, the node positions are displaced by the calculated linear wear. Most reported studies apply a constant wear factor, but it has been shown that the wear factor of metal on UHMWPE varies depending on the contact stress. This limitation was

\begin{equation}
\delta h = K_w \cdot \sigma \cdot S
\end{equation}

addressed by Onişoru et al. (7), who derived an equation to represent the relationship between contact stress and the wear factor, and applied this to their wear calculations, and reported an improved accuracy. Lui et al. (8; 9) used a similar approach but also took account of cross-shearing effects to predict wear, based on work by Kang et al. (10).

\[ \delta h_{node} = K_u \sum_{i=1}^{n} \sigma_i S_i \Delta t_i \]  

(1)

The majority of reported numerical wear studies for UHMWPE use linear isotropic material models to represent the material behaviour (Table 1), which is a simplification of the material properties for both short and long term time behaviour, such as polymers, rubbers, biological tissues and soils (19; 20; 21; 22); these kind of models have also been used to reproduce the behaviour of complex engineering components such as epoxy microbeam modeled with the FE method (23; 24; 25) and the influence of the temperature on mechanical parameters has been investigated (28). Free energy and state expressions for power-laws relaxation/creep functions are discussed in (26; 27). A three dimensional fractional viscoelastic theory has been derived and discussed in (29). Furthermore, the implementation in commercial FE software of a range of fractional viscoelastic models including fractional Maxwell, Kelvin–Voigt and Zener has been presented in (30). The purpose of the present study was to investigate whether the application of a viscoelastic material model to represent UHMWPE in an FE model alters the predicted wear. A fractional viscoelastic material model was fit to experimentally derived data (which have not been presented elsewhere), and then applied to a finite element model of a mobile unicompartamental knee replacement (The Oxford Knee, Zimmer-Biomet) to examine the influence on wear. We report differences in the predicted wear for a simple ramp–loading scenario as a preliminary study, with a view to increasing the model complexity as future work.

### Materials and Methods

#### Development of the fractional viscoelastic material model

In classical viscoelasticity the constitutive behaviour is obtained by combining the feature of springs (elastic elements) and dashpots (viscous elements). The mechanical models obtained with this approach are characterised by exponential relaxation and creep functions. However, at the beginning of the twentieth century it was observed that the creep and relaxation of many polymers is well fitted by power law functions (31) (with power lying in the range 0 to 1). In the frame of linear viscoelasticity, the Boltzmann superposition principle (32) is assumed to be valid. If power law creep/relaxation functions of the following types are assumed, the Boltzmann superposition principle leads directly to a constitutive law involving the so called fractional operators (Equation 2a and Equation 2b).

\[ R(t) = \frac{C_\alpha t^{-\alpha}}{\Gamma(1-\alpha)} \]  

(2a)

\[ C(t) = \frac{t^\alpha}{C_\alpha \Gamma(1+\alpha)} \]  

(2b)

These are nothing but than integro-differential operators of real order defined as convolution integrals with power law kernel (35); in viscoelasticity the order of integrals/derivatives is in the range 0 to 1. Integral equations provide more general solutions with respect to differential equations, a more extended discussion on integral operators and integrability conditions may be found in (33; 34). In Eqs. (2) \( R(t) \) and \( C(t) \) denote the creep and relaxation function, respectively, \( C_\alpha \) and \( \alpha \) are parameters, with \( 0 \leq \alpha \leq 1 \) and correspondent with order of derivative (or integral), and \( \Gamma(\cdot) \) is the Euler gamma function. The parameter \( C_\alpha \) is the

Viscoelastic material behaviour (creep, stress–relaxation, as well as a "fading" memory effect) can be represented by a combination of elastic behaviour (springs) and viscous behaviour (dashpots). The Maxwell or Kelvin–Voigt models are examples of spring and dashpot models; these have the advantage of fast implementation and can describe time–dependent behaviour but cannot accurately represent polyethylene. Increasing complexity, with multiple springs and dashpots in different arrangements (such as Zener models) can capture the creep and relaxation behaviour but are computationally very demanding. An alternative approach is the use of fractional viscoelastic material models,
viscoelastic modulus which dimension is anomalous because it depends on the parameter $\alpha$ that is a real number; the parameter $\alpha$ controls the time scale and the shape of the creep and relaxation functions.

The most simple model is the springpot, often represented as a rhombus (see Fig. 1). The constitutive equation of this model can be written as (36; 37)

\[ \sigma(t) = C_0 (D^\alpha \varepsilon)(t) \]  
\[ \varepsilon(t) = \frac{1}{C_0} (I^\alpha \sigma)(t) \]  

where $(D^\alpha \varepsilon)$ and $(I^\alpha \sigma)$ are the Caputo’s fractional derivative and the Riemann-Liouville fractional integral (35), respectively. For the simplicity of the notation, in the following the Caputo’s fractional derivative will be denoted simply by $(D^\alpha \cdot)$

The main advantage of the springpot model is that it is able to reproduce the power law behaviour observed experimentally and that it has long fading memory in agreement with the real behaviour of many materials. Moreover, it has been demonstrated that the behaviour of the springpot can be reproduced in classical viscoelasticity only by means of infinite sequence of springs and dashpots (38; 39; 40).

It is to be noted that in Eq. (2) $R(0) = \infty$ and $R(\infty) = 0$, $C(0) = 0$ and $C(\infty) = \infty$. However, experimental tests with many viscoelastic materials have revealed that often the relaxation and creep functions exhibit an initial ($t = 0$) and/or a long term ($t \to \infty$) finite value. For this reason the springpot model is often used in combination with one or more springs. Experimental tests on UHMWPE considered in this work are well reproduced by a springpot in series with a spring, namely a Fractional Maxwell model (depicted in Fig. 1). This result has been obtained by the authors in the experimental campaign described in the next section and is also confirmed by previous works (41). The constitutive law of the Fractional Maxwell model is written as follows.

\[ (D^\alpha \sigma)(t) + \frac{E}{C_0} \sigma(t) = E(D^\alpha \varepsilon)(t) \]  

where $E$ is the Young modulus related to the spring. The relaxation and creep functions of the fractional Maxwell model can be easily obtained as:

\[ R(t) = EE_0(1 + \alpha) \]  
\[ C(t) = \frac{1}{E} + \frac{t^\alpha}{C_0 \Gamma(1 + \alpha)} \]

being $E_0(\cdot)$ the one parameter Mittag-Leffler function defined as [citare Podlubny]

\[ E_0(z) = \sum_{k=0}^{\infty} \frac{z^k}{\Gamma(1 + \alpha k)} \]  

Eqs. (4) and (5) are related to a unidimensional model; indeed, Eq. (5b) has been assumed as a basis for the fitting of the experimental test described in the next section. However, for the finite element analysis a three dimensional model has to be defined. Assuming that the material is isotropic, only two relaxation or creep function are needed in order to characterize the three dimensional behaviour of the material, one describing the pure volumetric behaviour and the other one describing the pure shear behaviour (43; 44; 29). In compact form the terms of the relaxation matrix are written:

\[ R_{ijkh}(t) = \left( K_R(t) - \frac{2}{3} G_R(t) \right) \delta_{ij} \delta_{kh} \]

\[ + G_R(t) \left( \delta_{ik} \delta_{jkh} + \delta_{ih} \delta_{jk} \right) \]

Figure 1. Schematic illustration of the fractional Maxwell model.
homogeneous. For this reason the material can be considered linearly viscoelastic at the least up to 5 MPa of applied stress. This fact was confirmed by results published in (45) where it is shown that UHMWPE may be considered linear up to 10 MPa.

The maximum tensile stress \( \sigma_0 \) was reached after 4 minutes of ramp loading. The stress was maintained for 6 hours, after which the load was reduced to zero over a period of 4 minutes, and the samples were left to recover for 6 hours (Figure 3).

The fitting of experimental data has taken into account the exact history of stress described above and to this purpose it is written as:

\[
\sigma(t) = \frac{\sigma_0}{t_0} \left\{ \left[ t - (t - t_0)U(t - t_0) \right] - \left[ (t - t_1)U(t - t_1) - (t - t_2)U(t - t_2) \right] \right\}
\]

(8)

where \( t_0 = 4 \) minutes is the time at the end of the loading ramp, \( t_1 = 364 \) minutes is the time at the end of the creep phase, \( t_2 = 368 \) minutes is the time at the end of the unloading ramp and \( U(t) \) is the unit-step function. By assuming the creep function of Eq. (5b), the history of stress of Eq. (8) generates the following theoretical history of strain

\[
\epsilon(t) = \frac{\sigma_0}{E t_0} \left\{ \left[ t - (t - t_0)U(t - t_0) \right] - \left[ (t - t_1)U(t - t_1) - (t - t_2)U(t - t_2) \right] \right\} + \frac{\sigma_0}{C_\alpha t_0} \left\{ \left[ t^{1+\alpha} - (t - t_0)^{1+\alpha}U(t - t_0) \right] \right\} - \left[ (t - t_1)^{1+\alpha}U(t - t_1) - (t - t_2)^{1+\alpha}U(t - t_2) \right] \}
\]

(9)

The values of the obtained parameters \( E, C_\alpha \) and \( \alpha \) are reported in Table 3. The parameters related to the three-dimensional constitutive law \( (G, G_\alpha, \alpha, K, K_\beta \) and \( \beta \)) are reported in Table 4. These have been obtained by considering a constant Poisson’s ratio \( \nu = 0.46 \) (value commonly considered for UHMWPE) and the following well-known relationships has been used:

\[
G = \frac{E}{2(1 + \nu)} \quad (10a)
\]

\[
K = \frac{E}{3(1 - 2\nu)} \quad (10b)
\]

Analogous relationships have been used to obtain \( G_\alpha \) and \( K_\beta \) from \( C_\alpha \). The hypothesis of constant Poisson’s ratio implies also that \( \alpha = \beta = \alpha; \) this means that the volumetric and shear contribution evolve with the same time scale in our FE model. This fact is in disagreement with experimental results performed in the past with other polymers (42; 43) and it is possible that also for UHMWPE the time scales of the two contributions are different. However, the direct determination of the two time scales may be performed only if in the uniaxial creep test we are able to measure correctly not only the longitudinal strain but also the transverse strain. Another strategy is to perform two different creep tests, for example a uniaxial creep test and a torsion creep test. In this work it has not been possible to perform a double measure in the uniaxial creep test. However, for the scope of the work, that is to compare the predicted wear with a commonly used elasto-plastic model and with a fractional viscoelastic model, this approximation is acceptable.

**Finite element model definition**

The finite element model consisted of an UHMWPE unicompartmental knee bearing component (The Oxford
Partial Knee, Zimmer-Biomet), and an articulating femoral component modelled as an analytical rigid body. A medium sized component was modelled, as this is the size most commonly implanted; drawings of the component geometries have been previously published (46). The femoral component was a sphere of radius 24 mm, cut to a width of 20 mm. The upper articulating surface of the bearing conformed to the femoral component with a clearance of 0.2 mm. The thickness of the bearing in the centre was 3.5 mm, and the bearing was 34 mm long by 24 mm wide. Holes for marker wires were included and positioned 3 mm from the base of the bearing, and the marker wires themselves were represented as rigid cylinders of 1 mm diameter.

The components were assembled as shown in Figure 5; the femur, tibia, and tibial component did not contribute to the model but are included for illustrative purposes. The load was applied axially to the femoral component, perpendicular to the base of the bearing. The component was compressively ramp loaded to 1200 N over a period of 0.2 s, representing average loading during a step-up activity (47). The base of the bearing was constrained in the axial direction. Contact was defined between the femoral component and the upper surface of the bearing, a stiffness (penalty) contact algorithm was used with finite sliding, and a friction coefficient of 0.08 (48). Tie constraints were used to fix the marker wires within the bearing. The bearing was meshed with quadratic tetrahedral elements (C3D10M), and the converged mesh size was used; the determination of which is described in the section on mesh convergence.

The only material property assigned to the metallic components was density, as these were modelled as rigid bodies. The femoral component was modelled with a density of 8.387 g cm⁻³ to represent Cobalt-Chromium-Molybdenum alloy (49), and the marker wires were assigned a density of 4.42 g cm⁻³ for Titanium-6-Aluminium-4-Vanadium alloy (50). A subroutine was created to apply the fractional viscoelastic model described in the previous section. The input parameters used for the elasto-plastic material model were determined from standard tensile test results, where the sheet moulded GUR 4150 material was tested in accordance with ISO 527-3 using Specimen Type 2 geometry. The calculated parameters were a modulus of 855.2 MPa, a Poisson’s ratio of 0.46, and the plasticity parameters are summarised in Table 2. The material behaviour of the UHMWPE was assumed to be the same in compression as in tension for both models.

All models were created, solved, and post-processed using Abaqus finite element software (version 6.12, Dassault Systèmes, Paris, France). An explicit solver was used with an imposed time increment of $4 \times 10^{-6}$, validation of the mass scaling has been described previously (46).

**Quantification of wear**

Linear wear was calculated for the two different models using Equation 1. A wear factor of $1.06 \times 10^{-9}$ mm³ N⁻¹ mm⁻¹ was used, as reported by Maxian et al. (4; 5). The linear wear for each time increment was the maximum linear wear of all the nodes on the articulating surface. The volumetric wear was the sum of the linear wear of all the nodes on the articulating surface multiplied by the surface area ($766.2 \text{ mm}^2$).

The sliding distance ($S$) was calculated using the great-circle distance equation (Equation 11), which assumed that the sliding occurred around the circumference of the femoral component. The cartesian co-ordinates of the position of the nodes at the start and the end of the increment were converted to polar co-ordinates ($\phi_1, \lambda_1$ and $\phi_2, \lambda_2$, respectively) relative to the centre of the femoral component. The femoral component radius (24 mm) was used as the sphere radius (R), as the articulating surface of the design is spherical.

$$S = 2R \sin^{-1} \left[ \sin^2 \left( \frac{\phi_2 - \phi_1}{2} \right) + \cos(\phi_1) \cos(\phi_2) \sin^2 \left( \frac{\lambda_2 - \lambda_1}{2} \right) \right]^{0.5} \quad (11)$$

**Mesh convergence**

The mesh convergence was performed for the linear wear and volumetric wear output. The mesh seeding densities examined ranged from 2.0 mm to 5.0 mm, with 0.5 mm intervals, which created between 115 and 526 nodes on the articulating surface. Both the linear wear and volumetric wear
converged at a mesh size of 3.5 mm (Figure 6). Convergence was defined as when the result was within 30% of the next three smaller mesh sizes.

$\text{(a) Linear wear} \quad \text{(b) Volumetric wear}$

Figure 6. Variation of the calculated wear for different mesh densities. A mesh size of 3.5 mm was deemed converged (189 nodes).

Results

Definition of the fractional viscoelastic material model

The results of the creep–recovery experimental tests were fitted to the fractional viscoelastic Maxwell model as shown in Figure 4. The fitted parameters are summarised in Table 3. It can be seen that the parameters were of a good fit to the experimental data. These data were then converted into the parameters necessary for the fractional viscoelastic model as described in the previous section, and these are summarised in Table 4.

(b) Volumetric wear

Figure 7. Calculated total linear (a) and volumetric (b) wear for the elastoplastic material model and the fractional elastic material model. Results using a constant wear factor of $1.06 \times 10^{-9} \text{ mm}^3 \text{ N}^{-1} \text{ mm}^{-1}$, and the Onisoro wear factor which used a variable wear factor calculated from the contact stress ($7.99\sigma^{-0.653}$).

UHMWPE was almost 10 times greater than that predicted using an elastoplastic material model (Figure 7). When the wear factor was calculated using the Onisoro equation (7), this difference was even greater but the overall predicted wear was reduced.

\centering
\includegraphics[width=\textwidth]{figure}
\caption{Total linear (a) and volumetric (b) wear for the elastoplastic material model and the fractional viscoelastic material model. Results using a constant wear factor of $1.06 \times 10^{-9} \text{ mm}^3 \text{ N}^{-1} \text{ mm}^{-1}$, and the Onisoro wear factor which used a variable wear factor calculated from the contact stress ($7.99\sigma^{-0.653}$).}
\end{figure}

The cumulative increase in wear (both linear and volumetric) was approximately linear for the elastoplastic material model (coefficient of determination = 0.912 for linear wear, and 0.834 for volumetric wear). Whereas the viscoelastic model deviated from linearity at higher loads (Figures 8 & 9).

Stress analysis

The overall stress within the bearing was increased when the UHMWPE was represented as a viscoelastic material, but in particular a difference was noticed in the stress on the contact surface and in the contact region. Figure 10
Figure 8. Cumulative wear calculated throughout the loading step. Results are shown for the Elastoplastic material model, and the fractional viscoelastic material model, calculated using a constant wear factor of $1.06 \times 10^{-9}$ mm$^3$ N$^{-1}$ mm$^{-1}$.

illustrates a cross-section through the centre of the bearing for the two different material models. It can be seen that in the viscoelastic model the stress is more concentrated around the articulating surface, whereas in the elastoplastic material model the stress is evenly distributed through the thickness of the bearing.

Discussion

The results of this study have demonstrated a clear difference in the wear prediction from a finite element model of an UHMWPE component when using a viscoelastic material model definition compared with an elastoplastic model. It is known that elast–plastic material models will underestimate stress due to the stress-relieving effect of plasticity. However, numerous authors have used linear elastic material models to predict wear and the results have correlated well with either experimental wear test data, or clinical data. It is therefore unexpected that a more representative material model can have such a large influence on the predicted wear.

One possible reason for this discrepancy could be the wear factor. As shown in Table 1, a wide range of wear coefficients are reported in the literature; values range from $0.00002 \times 10^{-9}$ mm$^3$ N$^{-1}$ mm$^{-1}$ to $1.2 \times 10^{-9}$ mm$^3$ N$^{-1}$ mm$^{-1}$.
The majority of wear factors are calculated from pin-on-disk experiments which can have a simplified loading scenario compared to in vivo loading, but some studies have used simulator wear results, and clinically derived data to calculate wear factors (3) which are likely to be more representative. Nevertheless, there is a need for more research to accurately determine the wear factor of metal on UHMWPE for different situations to ensure the accuracy of numerical wear predictions.

Despite being a more accurate representation of the material behaviour, it may be that the increased wear predicted by the viscoelastic model is not representative of reality. UHMWPE is known to harden due to alignment of molecular chains under cyclic loading, and also will oxidise over time in vivo. Neither the viscoelastic model, nor the elastoplastic model, takes into account the hardening. Including hardening effects into the model would reduce the wear rate. It could be that inclusion of kinematic hardening into the material model, or alteration of the wear factor with loading cycles could create a more realistic prediction of wear. Use of the wear factor to represent so called "running in wear" was reported by Liu et al. (51), who examined wear of metal–on–metal hip replacements using finite element analysis. The wear was calculated by defining the wear coefficients, one for short–term wear, and one for long–term wear. It may be possible to use a similar methodology to represent hardening and sub-surface oxidation of UHMWPE with time while maintaining computational efficiency.

Another factor to consider in the wear calculation is determination of the sliding distance. In the present study the sliding distance was calculated using the great–circle distance equation, which was possible due to the conforming nature of the articulating surfaces and the spherical geometry. In the design of the Oxford Unicompartmental Knee there is a 0.2 mm clearance between the femoral component and the bearing. In the present study, because the femoral component was modelled as a rigid part, it was valid to assume that where contact occurred on the bearing surface, that this clearance must have been closed by deformation of the bearing. However, if material properties had been assigned to the femoral component use of the great–circle distance equation could have introduced errors. Studies in the literature often do not mention how sliding distance has been calculated. Teoh et al. mention using the great–circle distance equation to calculate the sliding distance. Other studies calculate the sliding distance based upon a defined rotational or translational displacement (14), but these assume no change in the component geometry. However, the influence of this assumption would be expected to be minor in the case of large displacements and small wear.

In this study the fractional viscoelastic model predicted approximately 10 times more linear wear compared to the elastoplastic material model, and over one loading cycle the difference in magnitude of predicted wear was 0.04 pm. A patient after knee arthroplasty typically walks 1 million steps, and so in 1 year the difference in predicted linear wear would be 0.04 μm (assuming a linear increase in wear with time). This represents a large difference clinically in terms of both UHMWPE wear particles within the joint, and damage to the component.

Conclusions

In conclusion, this study has shown the use of simplified material models to represent polyethylene to predict wear introduces significant (up to 10 times) error in the calculated wear volume. In contrast, the fractional viscoelastic material model, which was defined from experimental data, predicted concentrated stresses on the articulating surface, which is matches well with damage observed in retrieved components (52). Use of such accurate material models in finite element models of joint replacements could prove to be a cost-efficient, reliable way to predict wear and aid optimal implant design.

G.A. wish to acknowledge support from the University of Palermo to visit the University of Oxford, during which period this research was conducted.

Author Contributions

O.B. and E.P designed the study. G.A. and O.B. performed the mechanical testing and created the fractional viscoelastic material model. E.P. developed the finite element model and G.A. implemented the fractional viscoelastic material code. E.P performed the data analysis and wrote the paper and O.B. and G.A. edited the manuscript.

Conflict of interests

The authors declare no conflict of interest.
