Abstract

Cell walls surround all plant cells, and their composition and structure are modified in a tightly-controlled, adaptive manner to meet sometimes opposing functional requirements during growth and development. The plant cell wall integrity (CWI) maintenance mechanism controls these functional modifications as well as responses to cell wall damage (CWD). We investigated how the CWI system mediates responses to CWD in Arabidopsis thaliana. CWD induced by cell wall–degrading enzymes or an inhibitor of cellulose biosynthesis elicited similar, turgor-sensitive stress responses. Phenotypic clustering with 27 genotypes identified a core group of receptor-like kinases (RLKs) and ion channels required for activation of CWD responses. A genetic analysis showed that the RLK FEI2 and the plasma membrane–localized mechanosensitive Ca$^{2+}$ channel MCA1 functioned downstream of the RLK THE1 in CWD perception. In contrast, pattern-triggered immunity (PTI) signaling components, including the receptors for plant elicitor peptides (AtPeps) PEPR1 and PEPR2, repressed responses to CWD. CWD induced the expression of PROPEP1 and PROPEP3, which encode the precursors of AtPep1 and AtPep3, and the release of PROPEP3 into the growth medium. Application of AtPep1 and AtPep3 repressed CWD-induced phytohormone accumulation in a concentration-dependent manner. These results suggest that AtPep-mediated signaling suppresses CWD-induced defense responses controlled by the CWI mechanism. This suppression was alleviated when PTI signaling downstream of PEPR1 and PEPR2 was impaired. Defense responses controlled by the CWI maintenance mechanism might thus compensate to some extent for loss of PTI signaling elements.
Introduction

Plants adapt to diverse environments by modifying their architecture. The cell walls surrounding all plant cells are key elements enabling this adaptability and consist of different components including proteins and polysaccharides such as cellulose, hemicelluloses, pectins, and lignin (1). These components are synthesized in different subcellular compartments and have specialized functions. Cellulose is synthesized by plasmamembrane-localized cellulose synthase complexes and released into the adjacent extracellular space as strands that form microfibrils before being incorporated into the wall where they function as the main load-bearing element. The walls are also essential elements underlying growth, development, and resistance to biotic and abiotic stresses, all of which influence crop yield (2, 3). This is illustrated by mutations that improve yields of staple crops like maize and rice by affecting cell wall biosynthesis, homeostasis, polysaccharide modifications, and signaling components (4, 5).

Cell wall plasticity describes the ability of plant cell walls to adapt to dynamic and challenging growth conditions. Plasticity and the resulting recalcitrance in cell wall biochemistry and structure against targeted manipulation also represent a major challenge to producing energy from lignocellulosic biomass (6). The available evidence suggests that the plant cell wall integrity (CWI) maintenance system forms an integral element of cell wall plasticity (7–9). This mechanism seems to involve receptor-like kinases (RLKs) and ion channels that constantly monitor the state of the cell wall and initiate adaptive changes in both cellular and cell wall metabolism in response to cell wall damage (CWD) (10–12). Here we refer to any changes to cell wall structure or composition that impair CWI as CWD. Because CWD may be induced by various means, both ligand-mediated mechanisms and
mechanoperception could be involved in CWD detection. For example, pathogen-derived enzymes break down cell walls, which releases cell wall–derived fragments. This could lead to cell wall weakening, deformation, displacement of the cell wall relative to the plasma membrane and can eventually result in cell bursting due to the high turgor pressure of the cell (13, 14). The cell wall fragments, such as celllobiose or oligogalacturonides (OGs, fragments of pectic polysaccharides), can activate plant immune responses (15, 16). Whereas OGs are detected through wall-associated receptor kinases (WAKs), the receptors for celllobiose have not been identified (7). Mechansensitive systems may also be activated by CWD that compromises the structural integrity of the cell wall (17). In addition to the enzymatic actions of pathogens and mechanical damage caused by breakage or grazing, defects in cell wall biosynthetic processes can also cause CWD by preventing the production of load-bearing structural elements (18).

Although several candidate genes have been implicated in CWD perception, experimental evidence confirming their involvement is scarce (7, 10, 19). Amongst the candidates identified in Arabidopsis thaliana are two homologs of plasma membrane–localized RLK1-like proteins originally in Catharanthus roseus (CrRLK1Ls): THESEUS1 (THE1) and FERONIA (FER) (20, 21). Additionally the leucine-rich repeat (LRR) RLK MALE DISCOVERER 1 (MDIS1)-INTERACTING RECEPTOR-LIKE KINASE 2 (MIK2), WALL-ASSOCIATED KINASE 1 (WAK1) and WAK2, as well as the putatively stretch-activated, mechanosensitive Ca\(^{2+}\) channel MATING PHEROMONE INDUCED DEATH 1 (MID1)-COMPLEMENTING ACTIVITY 1 (MCA1) have also been implicated in CWI maintenance in Arabidopsis (22–26). MCA1 was originally identified through its ability to partially complement a Saccharomyces cerevisiae strain deficient for MID1-CCH1 (Mating pheromone–induced death1–calcium channel
homolog1), which is required for CWI maintenance in this yeast (22, 27). Homologs of MCA1 and THE1 have been identified in Oryza sativa (OsMCA1), Zea mays (NOD) and Marchantia polymorpha (MpTHE), suggesting that these proteins may participate in cell wall maintenance across the plant kingdom (28–30). A characteristic feature of THE1, FER, WAK1, and WAK2 is the presence of domains that may bind cell wall–derived epitopes or ligands (8, 10, 31). However, binding to cell wall components has been confirmed only for WAK1, WAK2, and FER (8, 21, 32). THE1, FER and MIK2 are required for resistance to the fungal pathogen Fusarium oxysporum f. sp. conglutinans, implicating CWI signaling also in biotic stress responses (25, 33).

CWD induced by the inhibition of cellulose production stimulates the compensatory production of the cell wall components callose and lignin, accumulation of the hormones jasmonic acid (JA), salicylic acid (SA) and ethylene, generation of reactive oxygen species (ROS), and activation of Ca2+-based signaling, implicating all of these processes in CWI maintenance (11, 23, 34–37). CWD in Arabidopsis thaliana promotes the generation of ROS in the apoplast - the space adjacent to the plasma membrane that contains the cell wall - by RESPIRATORY BURST OXIDASE HOMOLOGUE D (RBOHD) (23). The activity of RBOHD is regulated by both Ca2+-dependent and Ca2+-independent mechanisms, with the latter requiring BOTRYTIS-INDUCED KINASE 1 (BIK1), which is a substrate of BRASSINOSTEROID INSENSITIVE 1 (BRI1)-ASSOCIATED KINASE 1 (BAK1) and other RLKs during pattern-triggered immunity (PTI) (38, 39). BAK1 acts as a co-receptor for LRR-RLKs, and as such plays an important role in responses to pathogen-associated molecular patterns (PAMPs) such as flagellin, the flagellin-derived epitope flg22, elongation factor-thermo unstable (EF-Tu), and the EF-Tu-derived epitope elf18, as well as damage-associated molecular patterns
(DAMPs) such as the AtPep1 and AtPep3 peptides (40–42). AtPep1 and AtPep3 precursor peptides are encoded by the PROPEP1 and PROPEP3 genes, which are induced by pathogen infection and wounding (43). The precursor peptides are reportedly released into the apoplastic space where they are likely processed to give rise to the active form (43). Application of AtPep peptides enhances both expression of their own PROPEP genes, creating a positive feedback loop, and PTI-controlled defense responses. PTI and CWI maintenance may complement each other during plant defense, but such regulatory interactions between CWI and PTI signaling have not been characterized (44–46).

Here we investigated the responses to different types of CWD to understand the cellular events underlying CWD perception. We analyzed CWD responses in 27 Arabidopsis thaliana genotypes to establish the functions of candidate genes in CWI maintenance and performed genetic analyses to assess whether key CWI signaling elements belong to one or more signaling cascades. We found that CWD induced the expression of AtPROPEP1 and AtPROPEP3 as well as the release of a PROPEP3 fusion protein. In contrast, application of AtPep1 and AtPep3 repressed CWD-induced phytohormone production, thus identifying a mechanism through which PTI signaling and the CWI maintenance mechanism cooperate to regulate defense responses.

Results

CWD responses induced by different stimuli are osmosensitive

We used an Arabidopsis seedling–based model system to investigate how plants respond to different types of CWD and elucidate further the role of turgor pressure in CWD
CWD was induced using either Driselase, a mix of several cell wall–degrading enzymes from *Basidomycetes* sp., or isoxaben (ISX), a herbicide that blocks cellulose biosynthesis (13, 18). We chose Driselase because this enzyme mix is similar to the enzyme cocktail released by fungal pathogens during infection (47–49). Furthermore, the enzymes lead to cell wall fragmentation, thus directly causing CWD regardless of cell type, differentiation stage, or turgor pressure. We chose ISX because it inhibits cellulose production only in actively elongating cells (for example, in the root elongation zone). It causes CWD in conjunction with the naturally high turgor pressure of plant cells because it reduces the number of load-bearing cellulose microfibrils in the walls, thus making the cell wall susceptible to failure. This is illustrated by the suppression of ISX-induced lignin, callose, JA, SA accumulation, tissue lesion formation, and redistribution of carbohydrates by addition of osmotica like sorbitol or mannitol (11, 50). Similar effects have been also reported in yeast cells exposed to CWD, indicating the importance of turgor pressure in CWI maintenance (51).

First we investigated the effect of ISX or Driselase treatment on the morphology of *Wave 131Y* seedlings, which ubiquitously express membrane-localized yellow fluorescent protein (YFP), in the presence or absence of an osmoticum (sorbitol) in time-course experiments (52). Whole seedlings were grown submerged in liquid culture (11), and the media was exchanged for fresh media containing the ISX solvent DMSO, sorbitol, Driselase, ISX, Driselase with sorbitol, or ISX with sorbitol at the 0h time point. At 7h, epidermal cells in the root elongation zone of ISX-treated seedlings exhibited a swollen phenotype, which was reduced by co-treatment with sorbitol (fig. S1A). Driselase treatment resulted in degradation of the root tip (including the elongation zone) after 7h leaving behind only larger, already fully elongated cells for visualization (fig. S1B). This degradation was possibly enhanced by the addition of
osmoticum. Because the effects on roots were so pronounced after 7h of treatment, we did not investigate the phenotypic effects in roots at later time points. In cotyledons of ISX-treated seedlings, the plasma membrane marker signal was similar to that in cotyledons from DMSO controls after 7h but was lost in patches after 24h (fig. S2A, B). Sorbitol treatment alone had no effect on membrane marker intensity, but, when co-administered with ISX, restored the marker signal at the 24h time point. Driselase treatment resulted in the formation of patches lacking the membrane marker after 7h (fig. S2C). These patches seemed to be more pronounced after 24h and were not affected by the addition of sorbitol (fig. S2C, D).

After establishing the dynamics of CWD responses we used the same experimental setup to investigate cell death and the deposition of lignin and callose in cotyledons and the accumulation of JA and SA in whole seedlings (11). We included also isoxaben resistant1-1 (ixr1-1) and bak1-5 mutant seedlings in the studies. The ixr1-1 mutation causes an amino acid substitution in CELLULOSE SYNTHASE A3 (CESA3) that renders the protein resistant to inhibition by ISX (53), thus providing a control for ISX specificity. Plants carrying the bak1-5 allele are only impaired in immune responses triggered by LRR-RLKs but not in brassinosteroid-dependent signaling, making the plants a suitable control for detecting the involvement of either DAMPs (for example AtPep1) generated by CWD or PAMPs that are possibly present as contaminants in Driselase (54) and perceived by LRR-RLKs. Col-0 (wild-type) and bak1-5 seedlings that were mock (DMSO)-treated or treated with boiled (inactivated) Driselase exhibited no cell death in cotyledons (fig. S3A, B). ixr1-1 seedlings treated in the same manner exhibited a slight increase in cell death compared to Col-0. Treatment with ISX induced cell death in Col-0 and bak1-5, but not in ixr1-1 cotyledons compared to mock-treated
controls. Driselase treatment induced cell death in all genotypes examined. Sorbitol addition suppressed ISX-induced cell death but had no effect on Driselase-induced cell death.

We also analyzed compensatory lignin deposition in the cotyledons of seedlings that were treated with DMSO, ISX, boiled Driselase, or Driselase, with or without sorbitol, for 24h (fig. S3C). Lignin deposition was detectable after ISX treatment in vascular tissue areas in Col-0 and \textit{bak1-5} but not in \textit{ixr1-1} seedlings. Driselase-treated Col-0, \textit{bak1-5}, and \textit{ixr1-1} seedlings exhibited more ubiquitous lignin deposition. The addition of sorbitol reduced lignin deposition in all cases examined. \textit{bak1-5} and \textit{ixr1-1} cotyledons seemed more sensitive to Driselase treatment than Col-0 cotyledons based on cell death and lignin deposition phenotypes (fig. S3A, C).

Next we investigated compensatory callose deposition in the cotyledons of seedlings treated in the same manner. Whereas there was no detectable callose deposition in mock-treated or boiled Driselase–treated Col-0 and \textit{bak1-5} cotyledons, callose was deposited in \textit{ixr1-1} cotyledons subjected to these same control treatments (fig. S3D). Sorbitol alone had no effect on callose deposition in Col-0 and \textit{bak1-5} cotyledons but reduced callose deposition in both \textit{ixr1-1} treatment groups. ISX treatment induced callose deposition strongly in Col-0 seedlings, moderately in \textit{bak1-5} seedlings, but not in \textit{ixr1-1} seedlings. Sorbitol co-treatment with ISX reduced callose deposition in Col-0 and \textit{bak1-5}. Driselase treatment induced callose deposition in Col-0, but not in \textit{bak1-5} cotyledons, and did not induce more callose deposition in \textit{ixr1-1} seedlings than did boiled Driselase treatment (fig. S3D). \textit{bak1-5} plants also exhibit reduced flg22-induced callose deposition, suggesting that the lack of induction observed here is part of a more general defect (55). The lack of significant increase in callose deposition in
ixr1-1 was possibly caused by the combination of the substantial amount of basal callose deposition in mock conditions and limited callose induction by Driselase.

We next quantified phytohormones in Col-0, bak1-5, and ixr1-1 seedlings treated in the same manner as before. JA and SA abundances were low in mock-treated Col-0 and bak1-5 seedlings and slightly increased in ixr1-1 seedlings (Fig. 1A, B). ISX treatment induced JA accumulation in bak1-5 seedlings more than in Col-0 seedlings, but no induction was observed in ixr1-1 seedlings (Fig. 1A). ISX induced SA accumulation in both Col-0 and bak1-5 seedlings to a similar degree, but not in ixr1-1 seedlings (Fig. 1B). Co-treatment with sorbitol repressed ISX-induced JA and SA accumulation in Col-0 and bak1-5. Phytohormone amounts were lower in ixr1-1 seedlings treated with sorbitol or a combination of ISX and sorbitol than in mock-treated ixr1-1 seedlings, suggesting that sorbitol reduced stress in these plants (Fig. 1A, B). Driselase treatments induced JA and SA accumulation in Col-0, bak1-5, and ixr1-1 seedlings to different degrees compared to treatment with boiled Driselase (Fig. 1C, D). In contrast to ISX treatments, Driselase treatment reduced SA accumulation in bak1-5 compared to Col-0 (Fig. 1D). Although induction of both JA and SA by Driselase was less pronounced than induction by ISX in Col-0 and bak1-5 (Fig. 1A–D), sorbitol co-treatments nevertheless reduced or prevented accumulation of JA and SA in all genotypes examined. The results of these experiments suggest that responses to CWD are not restricted to a particular cell type (exemplified by lignin deposition in both vascular and epidermal tissues). Despite apparent differences in damage caused by ISX and Driselase, Col-0 seedlings exhibited similar osmo-sensitive responses to both types of CWD with respect to callose, lignin deposition as well as JA and SA accumulation. These observations suggest that both mechano- and osmo-perception may be required for induction of CWD responses. bak1-5 seedlings, which have
defects in PTI, exhibited distinct differences in their responses to the two CWD-inducing stimuli, suggesting some cross-regulation between PTI and CWI signaling.

Osmosensitivity distinguishes CWI signaling from DAMP- and PAMP-dependent responses

To investigate the regulatory processes responsible for the observed CWD-induced phenotypes, we first performed expression analysis of the defense marker *PLANT DEFENSIN1.2 (PDF1.2)* because it encodes a defense peptide that is involved in both CWD- and PTI-mediated processes (37, 56). In both Col-0 and *bak1-5* seedlings, treatment with boiled or active Driselase induced *PDF1.2* expression; however, *PDF1.2* was less highly expressed in boiled Driselase–treated *bak1-5* seedlings compared to boiled Driselase–treated Col-0, and it was more highly induced by Driselase in *bak1-5* than in Col-0 seedlings (Fig. 1E). This supports the hypothesis that BAK1 might contribute to the PTI-mediated recognition of factors in the enzyme preparation, which are not removed by boiling, but represses the response to CWD elicited by the active enzymes. To investigate the role of mechanoperception in the response to CWD, we analyzed the expression of a marker for mechanical stimulation (*TOUCH4, TCH4*) in ISX- and Driselase-treated Col-0 seedlings (57). ISX and active Driselase induced *TCH4* expression, whereas sorbitol co-treatments reduced it, providing support for an involvement of mechanoperception in the detection of CWD (Fig. 1F).

The results from the phytohormone measurements in *bak1-5* seedlings treated with ISX and Driselase with or without sorbitol, in conjunction with the results from the *PDF1.2* expression analysis, suggested that DAMP or PAMP signaling, or both, might also be
sensitive to turgor changes. Therefore we investigated a possible involvement of OG-induced signaling in turgor-sensitive CWI maintenance using gene expression analysis and phytohormone measurements (58). We examined the expression of RETICULIN OXIDASE (RET-OX) and CYTOCHROME P450, FAMILY 81, SUBFAMILY F, POLYPEPTIDE 2 (CYP81F2), both of which are induced by OG and the flagellin derivative flg22 (58), in Col-0 seedlings that had been treated with two different concentrations of OGs in the absence or presence of the osmoticum sorbitol. Expression of both genes was induced by OG treatments but was not sensitive to sorbitol co-treatment (fig. S4A, B). We also quantified JA and SA in seedlings treated in the same manner. Both OG and sorbitol treatments resulted in only minor changes in phytohormone amounts (fig. S4C, D). These results showed that OGs can be perceived by the seedlings in our assay and that OG-induced responses, unlike ISX- and Driselase-induced responses, are not osmosensitive, suggesting that CWD responses analyzed here do not involve OG-dependent signaling.

Next we quantified RET-OX and CYP81F2 expression and the amounts of JA and SA in seedlings treated with flg22, sorbitol, or both flg22 and sorbitol. RET-OX and CYP81F2 expression was not significantly increased by sorbitol treatment alone, increased moderately by flg22 treatment, and increased greatly in seedlings treated with flg22 plus sorbitol (fig. S4E, F). Treatments with sorbitol and flg22 resulted in changes in JA amounts that were at the lower limit of detection, though both sorbitol alone and flg22 plus sorbitol promoted JA accumulation (fig. S4G). Flg22 induced SA accumulation after 3h and 7h of treatment, and co-treatment with sorbitol enhanced SA accumulation after 7h (fig. S4H). These results showed that flg22-induced gene expression, JA and SA accumulation are turgor-sensitive. However, sorbitol treatments seem to enhance the flg22-induced responses, contrary to what we
observed with the responses to Driselase and ISX. These results suggest that turgor pressure is relevant for flg22-induced responses but that the underlying regulatory process is distinct from CWI maintenance signaling.

**Isoxaben and cell wall–degrading enzymes induce similar osmosensitive responses**

Driselase is a complex mix of enzymes that degrade several different cell wall polymers (59). To investigate whether the effects observed in Driselase-treated seedlings can be assigned to particular enzymatic activities, we obtained homogeneous preparations of the individual enzymes (xylanase, cellulase, pectinase) that, according to the manufacturer, account for the majority of the enzymatic activities in commercially-prepared Driselase. Initially we treated seedlings with increasing concentrations of the individual enzymes and measured phytohormone accumulation to establish optimal experimental conditions (fig. S5A, B). Xylanase did not induce phytohormone production, whereas cellulase induced only SA accumulation. Pectinase treatment increased the abundance of both SA and JA in seedlings in a concentration-dependent manner. Based on these tests, we focused primarily on pectinase and cellulase. JA or SA did not accumulate in seedlings treated with boiled enzymes or sorbitol (fig. 1G-J). Pectinase treatment induced accumulation of both JA and SA in an osmosensitive manner (fig. 1G, H). Because cellulase treatment alone did not induce JA accumulation, we quantified hormone accumulation after combining cellulase with either xylanase or pectinase. Seedlings treated with cellulase plus xylanase exhibited no increase in JA and a moderate increase in SA accumulation, similar to cellulase alone (Fig. 1I, J and S5B). Cellulase plus pectinase elicited JA accumulation, which was higher than in the seedlings treated with the individual enzymes (Fig. 1G, I, S5A). SA amounts were lower than
in pectinase-treated seedlings but higher than in those treated with cellulase alone (Fig. 1H, J, S5B). Sorbitol addition reduced phytohormone accumulation in all enzyme treatments examined. These results suggested that the combination of cellulase and pectinase is mainly responsible for the observed JA and SA accumulation in Driselase-treated seedlings. The differences in the effects of individual enzymes suggest that particular types of CWD may induce distinct phytohormone responses.

It is conceivable that a factor that is released or secreted from cells upon ISX or Driselase treatment is responsible for activation of the CWD responses observed. To test this hypothesis, we measured JA and SA accumulation in (i) \textit{ixr1-1} seedlings that had been incubated with supernatants from Col-0 seedlings pre-treated with ISX for 12h or 24h and (ii) in Col-0 seedlings incubated with boiled supernatants from Col-0 seedlings pre-treated with Driselase for 12h or 24h (fig. S6A, B). JA accumulation was barely above the detection limit in the seedlings treated with the different supernatants (fig. S6C). With respect to SA accumulation, only minor changes were detected compared to mock-treated samples (fig. S6D). These results suggested that ISX and Driselase treatments do not cause the release of a factor into the medium that is capable of inducing JA and SA accumulation. Taken together, the osmosensitivity and similarities in seedling responses to different types of CWD (enzymatic vs. ISX) suggest that different causes of CWD may stimulate cells similarly (or even in the same way), which in turn activates the same cellular responses.

**Mechanical and hypo-osmotic stress sensors mediate certain CWD responses**

The phenotypic data suggested that osmosensitive processes are an important element of the mechanism mediating CWD responses. Therefore we investigated whether genes
implicated in the perception of mechanical [MCA1, MECHANOSENSITIVE CHANNEL OF SMALL CONDUCTANCE (MSCS-LIKE) 4 (MSL4), MSL5, MSL6, MSL9, and MSL10], hyp-osmotic (MCA1, MSL2, MSL3), and hyperosmotic stress [ARABIDOPSIS HISTIDINE KINASE1 (AHK1), AHK2 AHK3, AHK4] were involved in CWI maintenance (17). We used plants harboring mutations in these genes and also included the1-4 mutants in this analysis because the1-4 has been described as a gain-of-function allele that affects the cellular response to the inhibition of cellulose biosynthesis (20, 60). This allowed us to test whether any stimulus perceived by THE1 was also sensitive to osmoticum and to place osmosensitive responses upstream or downstream of THE1-mediated signaling. We treated mutant seedlings with ISX, sorbitol, or a combination of ISX plus sorbitol and measured JA accumulation in whole seedlings and lignification at the root tip (fig. S7A, B). JA and lignin were selected for this analysis because they enabled us to assess two qualitatively different responses (phytohormone production and cell wall metabolism). For these experiments we used only ISX, because the analysis above had shown that JA accumulation and lignin production are activated similarly by ISX and Driselase in an osmosensitive manner. Only mca1 and msl2 msl3 seedlings exhibited reducedJA accumulation upon ISX treatment compared to the corresponding wild-type (Col-0 or Ws-2) controls (fig. S7A). ISX induced lignin deposition in all mutants and wild-type plants that were tested, but co-treatment with sorbitol reduced ISX-induced lignin accumulation (fig. S7B). Lignin deposition was reduced in mca1 and enhanced in msl4/5/6/9/10 (plants in which MSL4, MSL5, MSL6, MSL9, and MSL10 were all mutated), ahk1 and ahk2 ahk3 seedlings compared to the corresponding controls (Fig. 2A). These results confirm the requirement of MCA1 for ISX-induced JA and lignin accumulation (23) and indicate that MSL2 MSL3 are required for JA accumulation whereas
MSL4/5/6/9/10, AHK1 and AHK2 AHK3 only affect ISX-induced lignin production. In all genotypes examined (including the1-4) sorbitol co-treatments still reduced ISX-induced lignin and JA accumulation. This suggests that the effects of the sorbitol treatment could be due to turgor equilibration, illustrated by the shape changes in ISX-treated root epidermal cells (fig. S1A and previously reported in (61)) and would therefore not require any of the sensors tested (62). Turgor manipulation affects all the phenotypic effects of CWD that we examined, whereas supernatants from seedlings that had previously experienced CWD did not induce phytohormone production, the most sensitive readout of the response to CWD. This suggests that turgor-sensitive, non-secreted stimuli may activate CWD responses. The substantial accumulation of JA we observed in the1-4 seedlings supports the hypothesis that the plasmamembrane-localized RLK THE1 is involved in perception of these turgor-sensitive stimuli. This suggests that the stimuli indicating compromised CWI may consist of cell wall-bound epitopes that change conformation. Alternatively, mechanical distortion or displacement of the plasma membrane against the cell wall upon CWD, similar to the processes activating the CWI maintenance mechanism in Saccharomyces cerevisiae, are conceivable as stimuli (51).

**Phenotypic clustering identifies a core group of RLKs and ion channels mediating CWI maintenance**

Genes required for cell elongation, fertilization, and immunity have been implicated in CWI maintenance (3, 10, 19, 63). To gain further insight into the molecular mode of action of CWI maintenance and to establish which of the candidate genes are required and assess their relative importance in the process, we investigated knockout or gain-of-function alleles for 14
RLKs [THE1, CURVY 1 (CVY1), FER, HERCULES RECEPTOR KINASE 1 (HERK1), HERK2, ERULUS (ERU), WAK2, FEI1, FEI2, MIK2, BAK1, BAK1-LIKE 1 (BKK1), PEPR1, PEPR2, BIK1, and RECEPTOR-LIKE PROTEIN 44 (RLP44)]. The specific alleles of each gene, including a T-DNA insertion allele of WAK2 that we designated as WAK2-12 (fig. S8A-C), are noted in the figures and summarized in Table S2. We measured JA and SA accumulation in mock- and ISX-treated seedlings of these genotypes as well as in the osmosensing and mechanosensing ahk1, ahk2 and ahk3 (ahk2/3), mca1, msl2 and msl3 (msl2/3), and msl4/5/6/9/10 mutants and in the ISX-resistant ixr1 mutant (Fig. 2B, C and S9A-D). JA and SA accumulation was similar to the corresponding wild-type controls in all mock-treated genotypes with the exception of fer-5 seedlings, which already exhibited increased JA and SA accumulation in the mock-treated samples, in line with the multifunctional nature of FER (fig. S9A-D) (9, 64). Moreover, ISX-induced JA and SA accumulation were strongly increased in fer-5 compared to wild-type, suggesting that FER is not essential for perception of ISX-induced CWD (fig. S9B, D). We also investigated root growth and ISX resistance, which could potentially distort the analyses performed here, in each genotype and found no substantial deviations from wild-type, with the exception of bak1-5 seedlings showing somewhat shorter roots than wild-type seedlings and irx1-1 seedlings being resistant to ISX, as expected. (fig. S9E, F). We quantified lignin deposition in the root tip area using an image analysis–based approach to generate quantitative data that could be normalized and used for subsequent hierarchical clustering (Fig. 2A). The quantitative data for JA, SA, and lignin accumulation were integrated through hierarchical clustering to generate a global, standardized overview, allowing assessment of both relative importance and functions of individual candidates in CWI maintenance (Fig. 2D). Data for fer-5 were not included in the hierarchical clustering to avoid
distortion during data integration due to the increased amounts of phytohormones in mock-treated seedlings (fig. S9A, C). The results showed that knockouts in five PTI signaling elements (BAK1, BKK1, BIK1, PEPR1, PEPR2) enhanced JA and SA accumulation in response to ISX treatment. Whereas the WAK2cTAP dominant-active allele exhibited increased JA accumulation, wak2 seedlings showed only a slight and statistically insignificant reduction in JA accumulation, which might be caused by redundancy within this gene family (8). In parallel, fei2 and mik2 seedlings exhibited significant reductions in the CWD responses examined, implicating (in the case of FEI2) or confirming (in the case of MIK2, (25)) their involvement in CWI maintenance. Seedlings in which the CrRLK1L family members CVY1, HERK1 and HERK2 had been knocked out exhibited enhanced hormone responses, whereas eru seedlings were not strongly affected, and the1-1 seedlings exhibited reduced responses, implying functional divergence within the CrRLK1L family. Loss of RLP44, which is involved in cell wall-mediated activation of brassinosteroid signaling (63), did not affect the responses analyzed, suggesting that RLP44 not required for responses to ISX-induced CWD. In summary, the hierarchical clustering showed that among the genes we tested MIK2, MCA1, MSL2/3, FEI2, and THE1 are the most important ones for activation of ISX-induced CWD responses. Several of these proteins have been implicated in turgor- and mechano-perception and are located in the plasma membrane or plastid envelope, both of which are sub-cellular compartments that are particularly sensitive to changes in turgor and mechanical stimuli (19, 65).

**THE1 is a key signaling element mediating CWD- but not PAMP-induced responses**
We performed a genetic analysis to establish whether THE1, MCA1, and FEI2 are part of the same or different signaling cascade, using both a THE1 loss-of-function (the1-1) and a gain-of-function (the1-4) allele. We generated the mca1 fei2, the1-1 mca1, the1-1 fei2, the1-4 mca1, and the1-4 fei2 double mutants and measured the accumulation of JA, SA, and lignin in these mutant seedlings after mock and ISX treatments. JA, SA, and lignin phenotypes in mca1 fei2, the1-1 mca1, and the1-1 fei2 seedlings were not additive, but fei2 was epistatic to mca1, and the1-1 was epistatic to both mca1 and fei2 (Fig. 3A-C). Next we compared responses in the1-4 mca1 and the1-4 fei2 seedlings to the1-4 alone. JA and SA accumulation in the double mutants was reduced compared to the1-4 and similar to Col-0, whereas relative lignification was only reduced in the1-4 mca1 (Fig. 3D-F). These results suggested that MCA1 and FEI2 are both required for hormone signaling downstream of THE1, but only MCA1 is required for THE1-dependent lignification.

Phenotypic clustering and genetic analyses confirmed THE1 as a key regulatory component in CWI maintenance in response to ISX treatment. To determine whether THE1 was also required for Driselase-induced CWD, we quantified JA and SA accumulation in the1-1 loss-of-function and the1-4 gain-of-function seedlings treated with boiled or active Driselase. SA content was slightly increased in the1-4 controls treated with boiled Driselase compared to Col-0 seedlings, but JA content was similar in all genotypes (Fig. 3G, H). JA accumulation was reduced in the1-1 and enhanced in the1-4 seedlings upon treatment with active Driselase compared to Col-0 seedlings (Fig. 3G). SA amounts were increased similarly in Col-0 and the1-4 seedlings compared to boiled Driselase controls, and even further increased in the1-1 (Fig. 3H). These results suggest that a THE1-dependent mechanism controls JA accumulation
in response to both Driselase- and ISX-induced CWD, but indicate that additional factors control SA accumulation in Driselase-treated seedlings.

THE1 is critical for CWI signaling and also involved in pathogen resistance (25). Therefore it is conceivable that THE1 might also be involved in PTI. We tested this by treating the1-1 and the1-4 seedlings with flg22 and measuring subsequently SA accumulation (fig. S10). SA accumulated similarly in Col-0, the1-1, and the1-4 seedlings. In summary, these results suggest that THE1 acts upstream of MCA1 and FEI2, is required for both ISX and Driselase-induced JA production but is not required for PTI, implying that THE1 is specifically involved in CWI signaling.

**AtPEP1 and AtPEP3 repress CWD-induced phytohormone production**

To identify transcriptionally regulated elements of the CWI maintenance mechanism, Col-0 seedlings were mock- or ISX-treated and analyzed by RNA-Seq using mock- or ISX-treated ixr1-1 seedlings as controls. In Col-0 seedlings treated with ISX for 1h, 109 transcripts exhibited statistically significant differences from mock-treated controls (Data file S1). Although mock-treated ixr1-1 seedlings exhibited differences compared to mock-treated Col-0 at the transcriptome level, none of the ISX-regulated transcripts in Col-0 were differentially expressed in ISX-treated ixr1-1 seedlings (Data file S1). GO enrichment analysis detected an over-representation of genes implicated in phytohormone-dependent stress responses in ISX-treated Col-0 seedlings (Table S1). Among the differentially expressed transcripts were PROPEP1, PROPEP2, PROPEP3 and PROPEP4, which encode the precursors of the signaling peptides AtPep1–4 (fig. S11A) (43). PEPR1 has been shown to bind AtPep1–4, whereas PEPR2 binds only AtPep1 and AtPEP2 (43). This observation was intriguing given
that pepr1 and pepr2 seedlings exhibit enhanced JA accumulation upon ISX treatment (Fig. 2B). Gene expression analysis by qRT-PCR showed that PROPEP1 and PROPEP3 expression were particularly strongly induced by ISX (Fig. 4A). Time course expression analysis of PROPEP1 and PROPEP3 detected increases in expression over time in ISX-treated seedlings, suggesting that AtPep1 and AtPep3 might accumulate in response to ISX treatment (Fig. 4B). Expression of PROPEP1 and PROPEP3 was still increased in ISX-treated the1-1 seedlings, indicating that their induction was independent of THE1-mediated processes (Fig. 4C). AtPep1 enhances JA, SA and ethylene accumulation in response to wounding (66). To investigate whether AtPep1 also enhanced CWD responses, Col-0 seedlings were treated with different concentrations of AtPep1 alone or in combination with ISX before JA, SA, and lignin accumulation were measured. AtPep1 treatments alone did not induce JA and SA accumulation (Fig. 4D, E). Seedlings co-treated with ISX and AtPep1 exhibited reductions in ISX-induced JA and SA accumulation in a manner that depended on the concentration of AtPep1 (Fig. 4D, E). AtPep1 induced lignin deposition in Col-0 seedling roots in a distinctly different pattern than ISX treatment did whereas lignin deposition seemed to be additive in co-treated root tips compared to roots treated with either AtPep1 or ISX alone (fig. S11B).

To exclude indirect effects and determine whether the observed effects on AtPep1 were mediated by the established AtPep1 receptors, the experiments were repeated with Col-0, pepr1, pepr2, and pepr1 pepr2 seedlings. ISX-induced JA and SA accumulation was reduced in pepr1 and pepr2 seedlings upon co-treatment with ISX and AtPep1, similarly to the Col-0 seedlings (Fig. 4F, G). However, this was not the case in pepr1 pepr2 seedlings, in which co-treatment with AtPep1 did not counteract ISX-induced accumulation of JA and SA, suggesting that AtPep1 can inhibit ISX-induced phytohormone production through either PEPR1 or
PEPR2. Analysis of lignin deposition in seedlings treated with AtPep1, ISX, or both AtPep1 and ISX showed that PEPR2 is essential for AtPep1-induced lignin deposition but PEPR1 is not (Fig. 4H). This provided further support for differences between PEPR1 and PEPR2 with respect to signaling activities. We also investigated AtPep3, which binds to PEPR1 but not to PEPR2, and found that AtPep3 co-treatment with ISX had similar effects as AtPep1 co-treatment on JA and SA accumulation in Col-0 seedlings (Fig. 4I, J). However, AtPep3 did not induce lignin production as did AtPep1 (fig. S11C), which can be explained by the inability of AtPep3 to bind to PEPR2 (42). Because the fusion protein PROPEP3-Venus is secreted upon treatment with AtPep2 (67), we tested whether ISX treatment also induced PROPEP3-Venus secretion. Seedlings stably expressing pPROPEP3::PROPEP3-Venus were mock- or ISX-treated, and we immunoprecipitated the fusion protein from the growth medium (68). On a silver-stained polyacrylamide gel containing the protein preparations from the growth medium, bands of around 25 kDa were visible in preparations from both mock- and ISX-treated samples, consistent with the fusion protein being processed following secretion into the apoplast to release Venus alone (27 kDa) (Fig. 4K). A band corresponding to the size of the full-length fusion protein (PROPEP3-Venus, 37kDa) was only detected in the preparation from ISX-treated seedlings. Subjecting the proteins in these bands to peptide mass fingerprinting by liquid chromatography-coupled tandem mass spectrometry (LC-MS/MS) identified unique peptides corresponding to PROPEP3 and the VENUS tag with high confidence only in growth medium derived from ISX-treated seedlings (Fig. 4L, Data file S2). These results suggest that PROPEP3 is secreted from seedlings in response to ISX treatment.

Taken together, our data suggest that CWD induces the production of AtPep1 and AtPep3 through a mechanism that is independent of THE1 and seems to be regulated at the
transcriptional level through controlled expression of PROPEP1 and PROPEP3. The AtPep1 and 3 signaling process via PEPR1 and PEPR2 is redundantly organized because only pepr1 pepr2 seedlings are unresponsive to AtPep1-treatment. AtPep1 and AtPep3 seem to act as inhibitors of phytohormone accumulation in response to CWD, whereas they have been previously described exclusively as enhancers of PTI responses. These results suggest that the specific activities of AtPep1 and AtPep3 are context-dependent.

**Discussion**

Here we have shown that two different types of CWD result in similar, osmosensitive responses in different cell types possible through a non-mobile stimulus, such as an alteration in a cell wall component, structure, or mechanical properties. We identified a small group of molecular components, most of which are involved in the perception of mechanical or hypo-osmotic stress, that mediate both local (deposition of lignin) and systemic (phytohormone accumulation) responses to CWD. Simultaneously we observed that loss of PTI signaling elements, such as BAK1, BIK1, BKK1, PEPR1, and PEPR2, enhanced the responses to CWD. We showed that THE1, MCA1, and FEI2 belong to the same signaling cascade and that THE1 was involved in mediating responses to both Driselase and ISX-induced CWD but not PTI-associated SA accumulation. We found that CWD induced PROPEP1 and PROPEP3 expression in a THE1-independent manner and that a PROPEP3-VENUS fusion protein is released into the growth medium from seedlings in response to ISX treatment. Application of AtPep1 and AtPep3 repressed CWD-induced JA and SA accumulation in a concentration-dependent manner, and repression by AtPep1 depended on the activity of PEPR1 and
PEPR2. These results provide insights into the early events during CWD perception and the mechanisms regulating the cellular and systemic responses.

ISX and Driselase treatments resulted in similar responses in seedlings. Experiments with the individual cell wall–degrading enzymes found in Driselase and combinations thereof showed that pectinase and cellulase together caused overall the greatest JA accumulation, whereas SA amounts were lower than in seedlings treated with pectinase alone. Pectinase may increase the accessibility of cellulose to cellulase, thus facilitating the breakdown of this load-bearing cell wall component, and perhaps explaining the similarities in the observed responses to ISX, Driselase, and combined pectinase plus cellulase treatments. Sorbitol co-treatments dampened all the responses to both enzyme- and ISX-induced CWD, suggesting that CWD responses are induced by a stimulus that is sensitive to turgor pressure. Treatments with supernatants derived from seedlings exposed to ISX or Driselase induced neither JA- nor SA-accumulation in a manner similar to Driselase and ISX treatments, suggesting that the stimulus activating the CWD responses is not mobile. All the genes that we identified through phenotypic clustering as being required for responses to CWD have been implicated in signal transduction or the perception of hypo-osmotic, mechanical, or cell wall damage (9, 19, 65, 69). This provides further support that the initial stimulus, indicating CWD has occurred, could be physical (mechanical). Taken together, these observations suggest that CWD could result in distortion or displacement of the plasma membrane relative to the cell wall possibly caused by changes in the surface tension of the wall itself due to weakening of the load-bearing cellulose framework. These changes in turn could be detected by the CWI maintenance mechanism and lead to the observed responses.
CWD in vivo is often caused by developmental processes, such as cell elongation, abiotic stressors, such as drought or cold temperature, or a pathogen breaking down the cell wall as part of the infection process (7, 70). Each of these different sources of CWD requires specialized, adaptive responses. The data presented here suggest that CWI and PTI signaling may coordinately contribute to these adaptive responses. If plants experience CWD, initially both CWI and AtPep-dependent PTI signaling seem to be activated independently (Fig. 5A). Induction of PROPEP1 and PROPEP3 expression leads to the release of PROPEPs, which are probably processed in the apoplast to generate AtPeps that are perceived by the receptors PEPR1 and PEPR2 and contribute to increased PTI responses (Fig. 5A, red elements). In parallel CWD is perceived separately through the CWI maintenance mechanism, which enables plant cells apparently to detect mechanical- or osmotic-induced physical damage to their cell walls or the consequences thereof (Fig. 5A, blue elements). If CWD is derived from developmental processes or abiotic stress, activation of the PROPEPs might not be further enhanced because PAMPs are absent, and the responses would consequently be mainly mediated by the CWI mechanism. If CWD is derived from a cell wall–degrading pathogen, PROPEP activation would be enhanced by the simultaneous presence of PAMPs (Fig. 5A). This leads on the one hand to increased activation of PTI-controlled, targeted defense responses and on the other hand to active repression of CWI-controlled responses through PEPR1 and PEPR2. If PTI is impaired - or if PEPR1 and PEPR2 are inactive - activation of the tailored defense responses is not enhanced, but the CWI-controlled responses are not repressed (Fig. 5B). This means that basal defense responses (exemplified here by JA and SA accumulation) controlled by the CWI maintenance mechanism are enhanced to compensate for a reduction of PTI controlled responses.
To summarize, the results presented here suggest that PTI and the CWI maintenance mechanism both “detect” CWD in plant cells in different ways and modulate responses in an adaptive manner. Coordination between PTI and CWI maintenance signaling is apparently mediated by AtPep1 and AtPep3, which function in this context as repressors, not enhancers, of CWI signaling. The effects observed in the pepr1 pepr2 double-mutant seedlings suggest that the CWI maintenance mechanism acts as backup system for activating basal defenses in case PTI and activation of the regular defense responses are impaired. Because homologs of THE1, MCA1, and WAK2 have been identified in both monocotyledonous and dicotyledonous plants as well as in more ancient species, the CWI maintenance mechanism - and potentially its interactions with PTI-based defense responses - may be conserved throughout the plant kingdom (28–30).
Materials and Methods

Reagents

All chemicals and enzymes were purchased from Sigma-Aldrich unless stated otherwise.

Plant growth and treatments

Wild-type and mutant Arabidopsis thaliana strains used in this study were ordered from the Nottingham Arabidopsis Stock Centre (http://arabidopsis.info/) or obtained directly from the laboratories previously publishing them. Detailed information is listed in Supplemental Table S2. Seedlings were grown in liquid culture as described (23) with minor modifications. Thirty milligrams of seeds were sterilized by sequential incubation with 70 % ethanol and 50 % bleach on a rotating mixer for 10 min each and washed 3 times with sterile water. Seeds were then transferred into 250 mL Erlenmeyer flasks containing 125 mL half-strength Murashige and Skoog growth medium (2.1 g/L Murashige and Skoog Basal Medium, 0.5 g/L MES salt and 1 % sucrose at pH 5.7). Seedlings were grown in long-day conditions (16h light, 22°C and 8h dark, 18°C) at 150 μmol m⁻² s⁻¹ photon flux density on a IKA KS501 flask shaker at a constant speed of 130 rotations per min.

For all experiments, seedlings were grown for 6 days before treatment. The following products were used for treatments at the indicated final concentrations throughout the manuscript, unless stated otherwise: Isoxaben (600 nM; DMSO), mock (DMSO), Driselase (0.03% w/v; Sigma D8037), cellulase (0.09% w/v; Duchefa C8001), pectinase (0.09% w/v; Sigma 17389), xylanase (0.09% w/v; Sigma X2753), sorbitol (300 mM). For heat inactivation, enzymes were boiled for 10 min. Supernatants from treated Col-0 cultures were incubated with ixr1-1 seedlings (DMSO, ISX, ISX+S) or boiled for 10 min and incubated with Col-0 seedlings.
(DMSO+S, bDri, bDri+S, Dri, Dri+S). AtPep1 (ATKVAKQRGKEKVSSGRPGQHN), AtPep3 (EIKARGKNKTTPSSGKGGKHN), and flg22 (QRLSTGSRINSKDDAAGLQIA) peptides were obtained from Peptron (Daejeon) and dissolved in sterile water.

Confocal Laser Scanning Microscopy

WAVE 131Y (52) seedlings used to investigate structural changes in root and cotyledon cells after cell wall damage were placed on microscopy slides, covered with the same medium used for the treatment and imaged with a Leica SP8 confocal laser scanning microscope (CLSM). Four Z-stacks were taken for each of the conditions analyzed using HC PL APO 10x/0.40 DRY objective (EX 514 nm, BA 525-535), pinhole 0.7 airy units (AU) and gain 700V. Z-stacks were transformed in 2D images by using the maximum intensity projections (0, threshold) function on LAS X software. To highlight the cell outlines, Z-projection images were transformed in gray-scale using GIMP v2.8.22 and presented as insets.

Phytohormone Analysis

The jasmonic acid (JA) and salicylic acid (SA) contents of seedlings were analyzed as described in (71) with minor modifications. Seedlings were sampled at 7h after treatment, flash-frozen in liquid nitrogen and freeze-dried for 24h. Aliquots each containing six to seven milligrams of freeze-dried seedlings were ground with 5 mm stainless steel beads in a Qiagen Tissue Lyser II for 2 min at 25 Hz. Shaking was repeated after the addition of 400 μL extraction buffer (10 % methanol, 1 % acetic acid) with internal standards (10 ng Jasmonic-d₅ Acid, 28 ng Salicylic-d₄ Acid; CDN Isotopes) before samples were incubated on ice for 30 min and centrifuged for 10 min at 16,000 g and 4°C. Supernatants were transferred into fresh
tubes and the pellets were re-extracted with 400 μl extraction buffer without internal standards. Supernatants were combined and centrifuged 3 times to remove all debris prior to LC-MS/MS analysis. An extraction control not containing plant material was treated equally to the plant samples. Chromatographic separation was carried out on a Shimadzu UFLC XR, equipped with a Waters Cortecs C18 column (2.7 μm, 2.1 x 100 mm). The solvent gradient (acetonitrile (ACN) / water with 0.1 % formic acid each) was adapted to a total run time of 7 min: 0-4 min 20 % to 95 % ACN, 4-5 min 95 % ACN, 5-7 min 95 % to 20 % ACN; flow rate 0.4 ml / min. For hormone identification and quantification an AB SCIEX Triple Quad 5500 system was used. Mass transitions were: JA 209 > 59, D₅-JA 214 > 62, SA 137 > 93, D₄-SA 141 > 97.

**Callose Analysis**

Seedlings were sampled 24h after treatment and placed in 70 % (v/v) ethanol. For callose staining, samples were incubated in 0.07 M sodium phosphate buffer pH 9 for 30 min and in 0.005 % (w/v) aniline blue (in 0.07 M sodium phosphate buffer pH 9) for 60 min. Samples were washed with water, mounted in 50 % (v/v) glycerol and analyzed on a Nikon Eclipse E800 microscope using a UV-2A filter (EX 330-380 nm, DM 400 nm, BA 420 nm). Images were taken at 10x magnification and callose depositions quantified using ImageJ software.

**Lignin Analysis**

Lignification was investigated 12 h (root tips) and 24 h (cotyledons) after the start of treatments. Lignin was detected with phloroglucinol-HCL as described (23). Seedlings were photographed using a Zeiss Axio Zoom.V16 stereomicroscope. To assess the extent of lignin production in root tips, phloroglucinol-stained areas and the total root area imaged were
quantified using ImageJ (the same root length was maintained in all images taken). The relative lignified area was plotted as fold change compared to wild-type root tips.

**Cell Death Analysis**

Seedlings were sampled after 24h of treatment and incubated in trypan blue staining solution (0.025% trypan blue, 25% phenol, dissolved in equal volumes of lactic acid, glycerol, and water) for 6h at room temperature. Samples were de-stained in chloral hydrate overnight and transferred into 60% glycerol before microscopy. Images of the cotyledons were obtained with a Zeiss Axio Zoom.V16 stereomicroscope. The percentages of trypan blue-stained areas were quantified from cotyledons using ImageJ color thresholding.

**Root Growth Measurements**

Absolute root lengths were measured immediately prior to ISX treatment (0 h) to examine root growth phenotypes and 24h after start of treatment to determine ISX-dependent root growth inhibition (RGI). For calculation of %RGI the following formula was applied: \[1 - \frac{(ISX \ 24h \ - \ ISX \ 0h)}{(mock \ 24h \ - \ mock \ 0h)}\]*100.

**Hierarchical Cluster Analysis**

Hierarchical Clustering of ISX-dependent phenotypes was performed with Cluster 3.0 using the C Clustering Library v1.52 (72). All data from mutant seedlings was normalized to their corresponding wild-type control. Log\(_2\) transformed data was then used for average linkage clustering with an un-centered correlation similarity metric. Results were depicted using Java TreeView v1.1.6r4 and color-coded blue (less than in wild-type) or red (more than in wild-type)
Genotyping the WAK2 T-DNA insertion

Seeds were sown on a 6-well plate and grown in ½ MS1 for six days. Genomic DNA was extracted by grinding the plant material in a 2 mL Eppendorf tube with 5 mm stainless steel beads and 500 µL of extraction buffer (0.5 M NaCl, 50 mM EDTA, 0.1 M Tris-HCl, pH 8.0) in a Qiagen Tissue Lyser II for 1 min at 25 Hz. The lysate was centrifuged and 300 µL of supernatant was combined with 300 µL of isopropanol to precipitate the DNA. After centrifugation, the pellet was washed with 70% ethanol and dissolved in 100 µL of milli-Q water. One microliter of the isolated DNA was used for PCR reaction using Taq polymerase. The PCR program included an initial denaturation at 95 °C for 2 min followed by 30 cycles with 95 °C 30 s, 57 °C 30 s, 72 °C 1 min with final elongation at 72 °C for 2 min. The PCR products were run on 1% agarose gel containing Gel Red dye and imaged with a Syngene G-box imaging device.

qRT-PCR

Total RNA was isolated using a Spectrum Plant Total RNA Kit (Sigma-Aldrich). 2 micrograms of total RNA were treated with RQ1 RNase-Free DNase (Promega) and processed with the ImProm-II Reverse Transcription System (Promega) for cDNA synthesis. qRT-PCR was performed using a LightCycler 480 SYBR Green I Master (Roche) and primers (Supplemental Table S3) diluted according to manufacturer specifications. Four different reference genes (PP2A, ACT2, UBA1, GRF2) were examined to identify one exhibiting stable expression during ISX-treatment. ACT2 was the most stable and used in all experiments as a reference.
**RNA-Seq Analysis**

Total RNA was extracted using a Spectrum Plant Total RNA Kit (Sigma-Aldrich). RNA concentration was measured using a Qubit RNA HS Assay Kit (Thermo Fisher Scientific) and the integrity of the RNA assessed using an Agilent RNA 6000 Pico Kit. RNA Seq libraries were prepared using a TruSeq Stranded mRNA Kit (Illumina) according to the manufacturer's instructions. 500 ng total RNA was used as starting material.

First, index barcodes were ligated for identification of individual samples. mRNA purification, fragmentation, and cDNA synthesis was performed as described in (74). Exonuclease / polymerase was used to produce blunted overhangs. Illumina SR adapter oligonucleotides were ligated to the cDNA after 3' end adenylation. DNA fragments were enriched by 15 cycles of PCR reaction. The libraries were purified using the AMPure XP (Beckman Coulter), quantitated by qPCR using a KAPA Library Quantification Kit (Kapa Biosystems) and validated using a Agilent High Sensitivity DNA Kit on a Bioanalyzer. The size range of the DNA fragments were measured to be in the range of 200-700 bp and peaked around 296 bp. Libraries were normalized and pooled to 2.2 pM and subjected to clustering on NextSeq 500 high output flow cells. Finally, single-read sequencing was performed for 75 bp read lengths on a NextSeq 500 instrument (Illumina) according to the manufacturer instructions. Base-calling has been performed on the NS500 instrument by Illumina RTA v2.4.6. FASTQ files were generated using bcl2fastq2 Conversion Software v1.8.4. Each FASTQ file was subjected to quality control trough fastQC v11.1 before technical replicates were combined and an average of 13.1 million reads was produced for each library. The reads were then aligned to the *A. thaliana* genome (Ensembl v82) with STAR v2.4.1 in two-pass mode. On average,
96.2% of the reads aligned to the genome. The reads that aligned uniquely to the genome were aggregated into gene counts with FeatureCounts v1.4.6 using the genome annotations defined in Ensembl v82. Of the 32000 genes defined in the gene model, a total of 20750 genes were left for analysis after filtering out genes with a CPM (counts-per-million) value less than one in two or more samples.

The filtered gene count table was used as input to the Voom method of the limma R package v3.26.9 for differential expression (75). The samples were normalized using the TMM method before a linear model was defined (76). Differential expression between groups were tested by empirical Bayesian moderated t-tests and p-values were corrected for multiple testing by the Benjamini-Hochberg false discovery rate (FDR) adjustment. Statistical significance of pairwise comparisons was determined using a Student’s t-test. Genes with significantly altered expression after 1 h of ISX-treatment (Data File S1) were analyzed for GO enrichment using the PANTHER Overrepresentation Test (release 2016-07-15) and the GO Ontology database (Released 2017-02-28) on http://geneontology.org/. Results were filtered by p < 0.05 after Bonferroni correction for multiple testing. Data generated in the transcriptomics experiments are available under the following GEO submission ID: GSE109613.

**Extracellular PROPEP3-Venus assay and peptide mass fingerprinting**

Seedlings stably expressing pPROPEP3::PROPEP3-Venus were grown for 6 days prior to mock and ISX-treatment (68). After 24h, the growth medium was filtered through sterile miracloth and pH-adjusted to 7.5 with KOH. The number of seedlings per treatment was counted. Protease inhibitor cocktail (Sigma P9599) and phosphatase inhibitor cocktail 1 (Sigma P2850) were added to the medium. GFP-Trap agarose beads (Chromotek) were equilibrated according to manufacturer instructions and 50 μL bead slurry added to 2 mL
medium. The suspension was tumbled end-over-end for 2h at 4°C. Beads were recovered by centrifugation and washed as described. Proteins were dissociated from beads by incubating 10 min at 95°C in 2x Laemmli buffer and supernatants separated via 10% Acrylamide gel for SDS-PAGE. Proteins were visualized using a Bio-Rad Silver Stain Plus Kit according to manufacturer instructions and the gel was imaged on a Bio-Rad ChemiDoc XRS+ System. Gel bands were cut in smaller pieces (3-5 mm³) and were de-stained by incubation for 2 min in 150 μL ProteoSilver Destainer solution mix. The gel pieces were washed with ultrapure water and then shrunk with acetonitrile. They were reduced with DTT at 56°C, alkylated by iodoacetamide at room temperature in the dark, and – after being washed and shrunk – they were digested by trypsin at 37°C overnight. Peptides were collected, dried in a vacuum concentrator and reconstituted in 0.1% formic acid.

LC-MS/MS analysis was performed on an EASY-nLC 1200 UPLC system interfaced with an Q Exactive HF mass spectrometer via a Nanospray Flex ion source. Peptides were injected onto an Acclaim PepMap100 C18 trap column (75 μm i.d., 2 cm long, 3 μm, 100 Å) and further separated on an Acclaim PepMap100 C18 analytical column (75 μm i.d., 50 cm long, 2 μm, 100 Å) using a 60-min gradient (40 min 5-40 %B, 7 min 40-100 %B, 13 min 100 % B; where B is 0.1 % formic acid in CH3CN) at 250 nL/min flow. Peptides were analyzed in positive ion mode under data dependent acquisition (DDA) using the following parameters: Electrospray voltage 1.9 kV, HCD fragmentation with normalized collision energy 28. Each MS1 scan (200 to 2000 m/z, profile) was acquired at a resolution of 120,000 FWHM in the Orbitrap analyzer, followed by 15,000 FWHM MS2 scans (1.2 m/z isolation width, centroid) triggered for the 12 most intense ions, with a 15 s dynamic exclusion. Charge exclusion was set to unassigned, 1, and greater than 5.
Database search was performed in Proteome Discoverer 2.2 using Sequest HT engine against the proteome of Arabidopsis thaliana at UniProt (UP000006548, 2017-09-03), the amino acid sequence for PROPEP3-Venus and a list of sequences of usual protein contaminants. The search allowed up to 2 missed cleavages, precursor mass tolerance was 10 ppm and fragment mass tolerance was 0.02 Da. Carbamidomethyl (M +57.021 Da) was set as static modification and up to 4 dynamic modifications per peptide were allowed, possible modifications were: Oxidation (H,M,W +15.995 Da) and Deamidation (N,Q +0.984 Da). Validation was performed at PSM, Peptide and Protein level with high confidence set as 1% FDR and medium confidence representing 5% FDR. The mass spectrometry-derived proteomics data have been deposited to the ProteomeXchange Consortium via the PRIDE partner repository with the dataset identifier PXD009153 (77).

**Statistical Analysis**

Statistical significance was assessed using either Student’s *t*-test or one-way ANOVA followed by post-hoc analysis with Tukey’s HSD test. Statistical details of experiments are specified in the figure legends. Statistically significant differences are indicated by * * * p < 0.05, ** p < 0.01, *** p < 0.001 for Student’s *t*-test and different letters for one-way ANOVA / Tukey’s HSD test at α = 0.05. All statistical analyses were performed in IBM SPSS Statistics v24.

effector. *Cell Host Microbe* 7: 290–301.

Acknowledgements: The authors would like to thank Davi de Miranda Fonseca and the NTNU Proteomics and Metabolomics Core Facility (PROMEC) for support with protein and hormone analysis; the NTNU Genomics Core Facility (GCF) for support with RNA-Sequencing; Giulia De Lorenzo (University of Rome) for providing oligogalacturonides, Yusuke Saijo and colleagues at the Nara Institute for Science and Technology for making available transgenic plant lines. We are grateful to Martin Kuiper and John Mansfield for constructive comments on the manuscript. Funding: Financial support from the Deutsche Forschungsgemeinschaft EN 1071/1-1, HORIZON2020 (SugarOsmoSignaling) (T.E.), BBSRC (J.F. McK.), NTNU (M.V.), the Norwegian Financial Mechanism 2009-2014 Project Contract no. MSMT-23681/2015-1 (N.G.B./T.H.), the Gatsby Charitable Foundation (C.Z.), and the European Molecular Biology Organization (ALTF 657-2013) (D.V.d.D.) are gratefully acknowledged. Author contributions: T.E., N.G.B., M.V., L.V., T.H. contributed to experimental design, generated data and co-wrote the manuscript. J. McK. and F.A. contributed with experimental data. D.VdD. and C.Z. provided unpublished resources and contributed to the writing of the manuscript. Competing interests: The authors have no competing of interests. Data and materials availability: Data generated in the transcriptomics experiments have been deposited in the Gene Expression Omnibus (GEO, https://www.ncbi.nlm.nih.gov/geo/) with the identifier GSE109613. The mass spectrometry proteomics data have been deposited to the ProteomeXchange Consortium through the PRIDE partner repository (https://www.ebi.ac.uk/pride/archive/) with the dataset identifier PXD009153 (77).
Figure Legends

Fig. 1. Different types of cell wall damage induce similar osmosensitive responses.
Quantification of (A) jasmonic acid (JA) and (B) salicylic acid (SA), expressed as µg per g dry weight (gDW), in Col-0, bak1-5, and ixr1-1 seedlings that had been treated with DMSO (mock), DMSO and sorbitol (S), isoxaben (ISX), or isoxaben and sorbitol (ISX+S). (C) JA and (D) SA quantification in Col-0, bak1-5, and ixr1-1 seedlings treated with boiled (inactive) Driselase (bDri), bDri and sorbitol (bDri+S), Driselase (Dri) or Driselase and sorbitol (Dri+S). (E) Relative expression of PDF1.2 as determined by qRT-PCR in Col-0 and bak1-5 seedlings treated with bDri or Dri compared to untreated (NT) seedlings. (F) Relative expression of TCH4 in Col-0 seedlings treated as indicated. (G) JA and (H) SA quantification in Col-0 seedlings treated with boiled pectinase (bP), boiled pectinase and sorbitol (bP+S), pectinase (P), or pectinase and sorbitol (P+S). (I) JA and (J) SA quantification in Col-0 seedlings treated with the indicated combinations of boiled (b) or active preparations of cellulase (C), pectinase (P), xylanase (X), and sorbitol (S). All values represent means with error bars indicating SD. N = 4 (A–D), N = 3 (E–J). Letters a-d (A–J) indicate statistically significant differences according to one-way ANOVA and Tukey’s HSD test (α = 0.05) between treatments for each genotype. Asterisks (A–D) indicate statistically significant differences to the WT (Student’s t-test; ** p < 0.01; *** p < 0.001; ns, not significant).

Fig. 2. Phenotypic clustering identifies groups of genes involved in cell wall damage responses. Quantification of (A) root tip lignification, (B) jasmonic acid (JA) and (C) salicylic acid (SA) in the indicated mutant seedlings after treatment with isoxaben (ISX). Values represent means with error bars indicating SD and are expressed relative to the appropriate
wild-type (WT) control (Col-0 or Ws-2, depending on the genetic background of the mutant strain) from a representative experiment (dashed line). \( N \geq 10 \) (A). \( N = 4 \) (B, C); Asterisks indicate statistically significant differences between the mutant and WT (Student’s t-test, \( * p < 0.05 \)). Mutant lines are organized in functional groups (RLKs, Receptor-like kinases; CrRLK1Ls, Catharanthus roseus RLK1-like kinases; AHKs, Arabidopsis histidine kinases; Ion channels), and individual genotypes described in detail in Supplemental Table S2. (D) Hierarchical clustering of mutant phenotypes assigning functions in CWI maintenance to candidate genes based on their responses to ISX. Mutant phenotype data from (A–C) and fig. S9F (RGI, root growth inhibition) were normalized to WT controls and log2 transformed prior to average linkage clustering. Blue color indicates reduced ISX responses, and red color indicates increased ISX responses compared to WT.

Fig. 3. THE1 functions upstream of MCA1 and FEI2 and promotes responses to different types of cell wall damage. Quantification of (A) root tip lignification, (B) jasmonic acid (JA) and (C) salicylic acid (SA) following ISX treatment in wild-type (Col-0) and mutant seedlings carrying the indicated loss-of-function mutations. Quantification of (D) root tip lignification, (E) JA, and (F) SA following ISX treatment in Col-0 and mutant seedlings carrying the gain-of-function allele the1-4 or the1-4 in combination with the loss-of-function alleles mca1 or fei2. Quantification of (G) JA and (H) SA in Col-0, the1-1 (loss-of-function), and the1-4 (gain-of-function) seedlings treated with boiled Driselase (bDri) or Driselase (Dri). \( N \geq 17 \) (lignin), \( N = 4 \) (JA, SA). Letters a-e (A–F) indicate statistically significant differences between genotypes according to one-way ANOVA and Tukey’s HSD test (\( \alpha = 0.05 \)). Asterisks (G, H) indicate
statistically significant differences compared to the Col-0 control (Student’s t-test; * \( p < 0.05 \); ** \( p < 0.01 \); *** \( p < 0.001 \)).

**Fig. 4. Isoxaben induces PROPEP expression, and AtPep1 and AtPep3 repress responses to cell wall damage.** (A) Relative PROPEP1, PROPEP2, PROPEP3 and PROPEP4 expression determined by qRT-PCR in Col-0 seedlings treated with DMSO (mock) or isoxaben (ISX) for 1 h. (B) PROPEP1 and PROPEP3 expression in Col-0 seedlings at the indicated time points. (C) PROPEP1 and PROPEP3 expression in Col-0 and the1-1 seedlings after 1 h of mock or ISX treatment. Quantification of (D) jasmonic acid (JA) and (E) salicylic acid (SA) in Col-0 seedlings after co-treatment with either mock conditions or ISX plus 0, 1, 10, or 100 nM AtPep1. Quantification of (F) JA and (G) SA in Col-0, pepr1, pepr2, and pepr1 pepr2 seedlings after co-treatment with either mock conditions or ISX plus 10 nM AtPep1. (H) Root tip lignification in Col-0, pepr1, pepr2, and pepr1 pepr2 seedlings after co-treatment with either mock conditions or ISX plus 10 nM AtPep1 was visualized by phloroglucinol staining. Scale bar, 200 μm. Quantification of (I) JA and (J) SA in Col-0 seedlings after co-treatment with either mock conditions or ISX plus 0 or 10 nM AtPep3. All values represent means with error bars indicating SD. N = 3 (A–C, I–J), N = 4 (D–G), N ≥ 5 (H). Asterisks (A–C) indicate statistically significant differences compared to mock-treated controls (Student’s t-test; * \( p < 0.05 \)). Letters a–e (D–J) indicate statistically significant differences between treatments of each genotype according to one-way ANOVA and Tukey’s HSD test (\( \alpha = 0.05 \)). (K) Seedlings expressing PROPEP3-Venus were mock- or ISX-treated for 24 h. Proteins in the growth medium were immunoprecipitated, separated by SDS-PAGE, and stained with silver nitrate. The expected mass of PROPEP3-Venus is 37kDa, and the expected mass of
Venus alone is 27kDa. N = 2. (L) Numbers of unique PROPEP3-Venus peptides after trypsin digest identified by LC-MS/MS from silver-stained bands at around 25 kDa and 37 kDa. FDR, false discovery rate.

**Fig. 5. Model of stress response integration through CWI and PTI signaling. (A)**

Responses to cell wall damage caused by inhibition of cellulose biosynthesis (isoxaben, ISX) or enzymatic cell wall degradation (Driselase) in *Arabidopsis* depend on the receptor-like kinase (RLK) THE1. THE1 acts upstream of the ion channel MCA1 and the RLK FEI2 to stimulate the cell wall integrity (CWI) maintenance system. Independently, through an unknown mechanism, ISX treatment induces the expression of *PROPEP1* and *PROPEP3* (*PROPEP1/3*) and secretion of PROPEP3. Processing of PROPEP1 and PROPEP3 generate the host defense peptides *AtPep1* and *AtPep3* (*AtPep1/3*), which are damage-associated molecular patterns (DAMPs) that are also induced by pathogen elicitors during pattern-triggered immunity (PTI). *AtPep1/3* repress ISX-induced hormone accumulation through the *AtPep* receptors PEPR1 and PEPR2, suggesting an *AtPep*-dependent negative feedback mechanism. *AtPep* signaling also induces a positive feedback loop that enhances PTI. (B) If PTI-mediated induction of *AtPeps* or *AtPep* signaling is impaired, suppression of CWI signaling is alleviated, and the CWI maintenance pathway contributes to stress response induction to a greater extent than does PTI.
